## Rod Lift Successful In Horizontal Wells

By Ryan Orr

**BOTTOM RUN** The vast majority of artificial lift deployments have been in vertical wells that produce oil and gas from conventional (i.e., nonshale) reservoirs. The last decade, however, has seen a dramatic shift to unconventional oil and gas production from horizontal wells that stretch a lateral distance of one mile or more from the wellhead.

These long-distance laterals create unique production problems, such as liquid loading in the horizontal section of the wellbore. Horizontal wells typically cannot rely on natural wellbore pressure, including hydrostatic flow, to move low spots where water and other fluids can accumulate.

Removing these fluids is a major driver for artificial lift in lateral wells, and operators have been employing various solutions, including oil pumps, electric submersible pumps, and gas lift. While these methods have all been proven to boost production in vertical and deviated wells, there is less practical industry experience in deploying them effectively in horizontal wells.

Service providers have attempted to by tailoring lift solutions to meet the specific challenges of horizontal wells, so as to optimize production and extend operating life. One of the most successful production stimulation for unconventional wells is, in fact, gas lift (GR). It is being fluid to the surface through the existing pumping section of a surface pump attached to the rod string and downhole well completion.

Conventional artificial lift systems employ a sucker rod string consisting of individual sections that are joined by threaded connections at each end. A conventional

sucker rod string requires a coupling every 25-30 feet to connect two sections of rod together. This amounts to hundreds of connections in many wells.

Continuous sucker rod, which employs a continuous rod with no coupling, has replaced conventional sucker rods in GR and progressing cavity pumping systems in many applications. Continuous rods are a superior alternative to conventional sucker rods in many production scenarios.

Among the latest applications of continuous sucker rod lift systems are horizontal wells in the Permian Basin, where rod pumps are used for artificial lift in the vast majority of hydraulic wells, and where the increasing use of multiple unconventional oil resource plays continues to drive a dramatic increase in horizontal drilling activity.

### Design Delivers Benefits

Eliminating thousands of connections provides several well-known advantages over

conventional sucker rod strings. Each connection in a traditional sucker rod string introduces a point of possible failure. Unlike its coupling joints, which may promote fatigue failure, for example, and manual joint tightening can yield poorer control of proper makeup torque. In addition, a conventional rod introduces greater safety risks because two dedicated rig personnel are required to install and align the rods during makeup and hooking.

Continuous rod strings, by contrast, require only two threaded connections: one at the top and one at the bottom of the string. This significantly reduces risk from the thousands of joints that normally lie beyond of the string.

Another key feature of a continuous rod string is its uniform body design, which yields three major benefits. First, the uniform design helps reduce potential leaks between the tubing and the rod as it moves up and down during pumping.

The couplings in a conventional rod string set up concentrated contact loads
